#### Abstract

Heights or reduced levels are used in practically all aspects of construction: to produce ground contours on a plan; to enable the optimum design of road, railway or canal gradients; to facilitate ground modelling for accurate volumetric calculations; to deals with all applications require topographic data. Levelling can be defined as the operation required in the determination or, more strictly, the comparison of heights of points on the surface of the earth' [1]. Levelling is usually carried out as a separate procedure from that used for fixing planimetric position. It involves the measurement of vertical distance relative to a horizontal line of sight. Hence it requires a graduated staff for the vertical measurements and an instrument that will provide a horizontal line of sight. A datum is any reference surface to which the elevations of points are referred. The most commonly used datum is that of mean sea level (MSL). The vertical height of a point above or below a reference datum is referred to as the reduced level or simply the level of a point. Although, there are other conventional and modern methods for height determination but physical or direct observations of all points still tedious operation and time consuming. The Digital Elevation Model (DEM) is formed by 'sampling points over the land surface and using appropriate algorithms to process these points to represent the surface being modeled' [5]. In this research work, heights of sample area with $\mathbf{5 m} \times 5 \mathrm{~m}$ grid were determined. Then, about half of theses points were withdrawal and predicted from $10 \mathrm{~m} \times 10 \mathrm{~m}$ grid using number of four interpolation methods used to generate digital elevation models provided by SURFER package. Results showed that the accuracy of the DEMs generated were within the range of 0.8 m to 0.83 m and all tested interpolation methods approximately produce the same results.

Index Terms- DEM, Height, Interpolation, Levelling, Prediction and Surfer

## I. INTRODUCTION

SUURVEYING may be defined as 'the science of determining the position, in three dimensions, of natural and man-made features on or beneath the surface of the Earth. These features may be represented in analogue form as a contoured map, plan or chart, or in digital form such as a Digital Elevation model (DEM)' [7]. In engineering surveying, either or both of the above formats may be used for planning, design and construction of works, both on the
surface and underground. At a later stage, surveying techniques are used for dimensional control or setting out of designed constructional elements and also for monitoring deformation movements.

In the first instance, surveying requires management and decision making in deciding the appropriate methods and instrumentation required to complete the task satisfactorily to the specified accuracy and within the time limits available. This initial process can only be properly executed after very careful and detailed reconnaissance of the area to be surveyed. 'Data representation in analogue or digital form may now be carried out by conventional cartographic plotting or through a totally automated computer-based system leading to a paper or screen-based plot' [7].

## II. PORTRAYING THE LAND-SURFACE FORM

'The story of how terrain portrayal developed is a search for suitable methods. The problem has been that the most effective visual techniques did not give precise terrain information. Likewise, methods that gave accurate terrain values were the least effective visually' [2]. Number of methods can be used to represent terrain such as:

- Spot points
- Contour lines
- Shading
- Digital terrain model

## III. DIGITAL ELEVATION MODEL

A Digital Elevation (Ground) Model (DEM/ DGM); also known as Digital Terrain Model (DTM) 'is a three dimensional, mathematical representation of the landform and all its features, stored in a computer database. It can also be defined as a particular form of computer surface modeling which deals with the specific problems of numerically representing the surface of the earth. It referred originally to the use of cross-sectional height data to describe the terrain' [7]. Such a model is extremely useful in the design and construction process, as it permits quick and accurate determination of the coordinates and elevation of any point. The methods in common use are modelling by 'strings', 'regular grids' or 'triangulated irregular networks'. Regardless
of the methods used, they will all reflect the quality of the field data. A 'string' comprises a series of points along a feature and so such a system stores the position of features surveyed. The system is widely used for mapping purposes due to its flexibility, accuracy along the string and the ability to process large amounts of data very quickly. However, as the system does not store the relationship between strings, a searching process is essential when the levels of points not included in a string are required. Thus the system's weakness lies in the generation of accurate contours and volumes [7].

The 'regular grid' method uses appropriate algorithms to convert the sampled data to a regular grid of levels. If the field data permits, the smaller the grid interval, the more representative of landform it becomes. Although a simple technique, it only provides a very general shape of the landform, due to its tendency to ignore vertical breaks of slope. Volumes generated also tend to be rather inaccurate.

Fig. 1: Regular grid
'In the 'triangulated irregular networks' (TIN) method, 'best fit' triangles are formed between the points surveyed. The ground surface therefore comprises a network of triangular planes at various inclinations. Computer shading of the model provides an excellent indication of the landform. In this method vertical breaks are forced to form the sides of triangles, thereby maintaining correct ground shape. Contours, sections and levels may be obtained by linear interpolation through the triangles' [8].

Fig. 2: Triangulated irregular networks
Different sources of data for DEM are available such as:

- Field survey work
- Photogrammetry
- Satellite or documents scanners
- Digitized maps

Digital elevation model can be represented either by mathematically defined surface or by point or line images. Line data can be used to represent contours and profiles, and critical features such as streams, ridges shorelines, and breaks in slope.

DEM can be used in different application such as, photogrammetry, engineering, hydrography, military, computer-aided design and landscape processes.

## IV. INTERPOLATION

Interpolation can be defined as 'the procedure of predicting the value of attributes at unsampled sites from measurements made at point locations within the same area or region. Predicting the value of an attributes at sites out-site the area covered by exiting observations is called extrapolation' [6].

Interpolation is used to convert data from point observation to continuous fields so that the special patterns sampled by these measurements can be compared with the special patterns of other special entities.

Interpolation can be used when the data do not cover the domain of interest completely. This case may arise to represent variations in the elevation of the land surface (Digital Elevation Models - DEM).

## V. INVERSE DISTANCE TO A POWER

'The Inverse Distance to a Power gridding method is a weighted average interpolator, and can be either an exact or a smoothing interpolator' [8].

With Inverse Distance to a Power, data are weighted during interpolation such that the influence of one point relative to another declines with distance from the grid node. Weighting is assigned to data through the use of a weighting power that controls how the weighting factors drop off as distance from a grid node increases. The greater the weighting powers, the less effect points far from the grid node have during interpolation as shown in Eq. (1):

$$
\begin{equation*}
z=\frac{\sum_{i=1}^{n} z_{i} \times w_{i}}{\sum_{\mathrm{i}=1}^{\mathrm{n}} w_{i}} \ldots \ldots \ldots . \tag{1}
\end{equation*}
$$

Where,
$z$ is the predicted height,
$z i$ is the height of adjacent point,
$w i$ is the weight of each point and
$n$ represents the number surrounding points.
As the power increases, the grid node value approaches the value of the nearest point. For a smaller power, the weights are more evenly distributed among the neighboring data points.

Normally, Inverse Distance to a Power behaves as an exact interpolator. When calculating a grid node, the weights assigned to the data points are fractions, and the sum of all the weights is equal to 1.0 . When a particular observation is coincident with a grid node, the distance between that observation and the grid node is 0.0 , and that observation is
given a weight of 1.0 , while all other observations are given weights of 0.0 . Thus, the grid node is assigned the value of the coincident observation.

## VI. KRIGING

This method produces visually appealing maps from irregularly spaced data. 'Kriging attempts to express trends suggested in the data, so that, for example, high points might be connected along a ridge rather than isolated by bull's-eye type contours' [8].

Kriging can be either an exact or a smoothing interpolator depending on the user-specified parameters. It incorporates anisotropy and underlying trends in an efficient and natural manner. Mathematical form of kriging can be expressed as in Eq. (2).

$$
\begin{equation*}
z=\sum_{i=1}^{n} x i \times z(x i) \ldots \ldots \ldots \tag{2}
\end{equation*}
$$

## VII. NEAREST NEIGHBOR

'The Nearest Neighbor method assigns the value of the nearest point to each grid node. Alternatively, in cases where the data are nearly on a grid with only a few missing values, this method is effective for filling in the holes in the data' [8]. Nearest neighbor formula can be expressed as:

$$
\begin{equation*}
z=\frac{\sum_{i=1}^{n} z_{i}}{\mathrm{n}} \ldots \ldots \ldots \ldots \tag{3}
\end{equation*}
$$

Consider a set of Thiessen polygons (the dual of a Delaunay triangulation). If a new point (target) were added to the data set, these Thiessen polygons would be modified. In fact, some of the polygons would shrink in size, while none would increase in size. The area associated with the target's Thiessen polygon that was taken from an existing polygon is called the "borrowed area". The Natural Neighbor interpolation algorithm uses a weighted average of the neighboring observations, where the weights are proportional to the "borrowed area".

## VIII. LOCAL POLYNOMIAL

The Local Polynomial gridding method assigns values to grid nodes by using a weighted least squares fit with data within the grid node's search ellipse.
'Polynomial equations are used to represent the terrain surface in the global and patchwise methods of interpolation' [7].

The two dimensional complete $n$-th degree of polynomial equation can be given by:

$$
\begin{equation*}
z(x, y)=\sum_{i=1}^{n} a_{k} x^{i} y^{i} \tag{4}
\end{equation*}
$$

Where,
$a$ is coefficients, $i$ and $j$ are permuted accordingly ( $\mathrm{i}+\mathrm{j} \leq \mathrm{k}$ ). $x$ and $y$ are the planimetric coordinates of point.

## IX. SURFER

'Surfer is a powerful contouring, gridding, and surface mapping package for scientists, engineers, educators, or anyone who needs to generate maps quickly and easily. Producing publication quality maps has never been quicker or easier. Maps can be displayed and enhanced in Surfer. Adding multiple map layers, customizing the map display, and annotating with text create publication quality maps' [8].

Surfer is a grid-based mapping program that interpolates irregularly spaced XYZ data into a regularly spaced grid. Grids may also be imported from other sources. The grid is used to produce different types of maps including contour, vector, image, shaded relief, 3-D surface, and 3-D wireframe maps. Many gridding and mapping options are available allowing you to produce the map that best represents your data.

An extensive suite of gridding methods is available in Surfer. The variety of available methods provides different interpretations of the data, and allows choosing the most appropriate method for required needs. In addition, data metrics allow gathering information about gridded data. Surface area, projected planar area, and volumetric calculations can be performed quickly in Surfer. Crosssectional profiles can also be computed and exported.
'The grid files themselves can be edited, combined, filtered, sliced, queried, and mathematically transformed. For example, it can create an isopach map from two grid files. It will need the original surface grid file and the surface grid file after a volume of material was removed. Subtract the two surfaces to create an isopach map. The resulting map displays how much material has been removed in all areas' [8].

## X. MEASURMENTS AND RESULTS

In this research work, a sample area of $100 \times 100 \mathrm{~m}$ was selected and divided into $5 \mathrm{~m} \times 5 \mathrm{~m}$ grids.

Fig. 3: Study area
Levelling was carried out using total station instrument, assuming the coordinates of the south east corner of the area to be $(0 \mathrm{~m}, 100 \mathrm{~m})$ in Easting (E) and Northing (N)
respectively with 100 m height (H), i.e., Reduced Level (RL) as shown in appendix.

In order to estimate the accuracy of digital elevation model produced by surfer package, about half of the grid field data was omitted by assuming the grid to be $10 \mathrm{~m} \times 10 \mathrm{~m}$ rather than $5 \mathrm{~m} \times 5 \mathrm{~m}$. Then the omitted RLs were predicted using numbed of interpolation techniques provided by surfer.

Four interpolation methods were tested. These are:
i. Inverse distance to power
ii. Kriging
iii. Natural neighbor
iv. Local polynomial

In each test, predicted heights of points were compared with the original field heights and the differences were computed as:

$$
\begin{gather*}
\text { Differece }=\text { Predicted height } \\
\text { - Field heigh ... ... ... ... ... ... } \tag{5}
\end{gather*}
$$

In order to estimate the accuracy of digital elevation models generated by SURFER PACKAGE in each test, the Root Mean Square Error (RMSE) was used as accuracy estimation factor.

$$
\begin{equation*}
R M S E=\sqrt{\sum_{i=1}^{n} \frac{(\text { Difference })^{2}}{n-1}} \ldots \ldots . \tag{6}
\end{equation*}
$$

Where, $n$ is number of points.
The estimated accuracy- i.e., computed RMSE- for each method was found to be as shown in Table 1:

Table 1: Estimated accuracy of DEMs

| No. | Interpolation Method | RMSE (m) |
| :---: | :--- | :---: |
| 1 | Invers distance to power | $0.798 \approx 0.80$ |
| 2 | Kriging | $0.826 \approx 0.83$ |
| 3 | Natural Neighbor | $0.827 \approx 0.83$ |
| 4 | Local polynomial | $0.796 \approx 0.80$ |

## XI. CONCLUSION

- Although the study area was flat and resolution of the data was $10 \mathrm{~m} \times 10 \mathrm{~m}$ the accuracy of predicted digital elevation models was limited to the range of 0.80 to 0.83 m .
- Results also reflect that the digital elevation models generated by surfer package are suitable for preliminary study.
- Kriging and natural neighbor almost produce predicted heights of digital elevation models with the similar accuracy. On the other hand invers distance to power and local polynomial are of similar predicted results as well.
- Referring the maximum difference between the four studied methods $(0.03 \mathrm{~m})$ to the better accuracy obtained
$(0.8 \mathrm{~m})=3.75 \%$ it can said to be that the four methods approximately produce equal results.
